# Cut-off elevation angle and EOP results (a case of CONT05) <br> Zinovy Malkin <br> Pulkovo Observatory <br> August 23, 2007 

## Introduction

Earlier, the Goddard and Vienna groups have performed several studies of the impact of the cut-off elevation angle (CEA) on the geodetic results such as baseline length repeatability, troposphere parameters, and station heights. Those results were based on simulation.

In this memo, the results of processing of the CONT05 observations aiming at investigation of the impact of the CEA on the EOP estimates are presented. For this test, CONT05A observations were processed with different CEA ( $\mathrm{e}_{0}$ ) from 3 to $25^{\circ}$, keeping all other options the same as used during the routine processing:

Kalman filter mode,
random walk model for clocks, $\mathrm{PSD}=1.5 \mathrm{ps}^{2} / \mathrm{s}$,
random walk model for ZTD, $\mathrm{PSD}=0.25 \mathrm{ps}^{2} / \mathrm{s}$,
one NS and EW troposphere gradient estimate for the session.

## Test results

Results are shown in tables and figures below. Notation is the following:
Xp, Yp - terrestrial pole coordinates,
XYp - mean of Xp and Yp,
$\mathrm{Xc}, \mathrm{Yc}$ - celestial pole coordinates,
XYc - mean of Xc and Yc,
WADEV - weighted Allan deviation (the method developed in Malkin, 2007, accepted to Journal of Geodesy).
All the results related to the $\mathrm{Xp}, \mathrm{Yp}, \mathrm{Xc}$ and Yc are given in $\mu \mathrm{as}$, the results related to the UT1 are given in $\mu \mathrm{s}$.

The case of $\mathrm{e}_{0}=3^{\circ}$ includes all the observations since no observations were made at the elevation less than $4^{\circ}$.

The last raw of the tables (R) contain the results of the routine processing, without elevation cut-off, but with elevation depending weighting using the weight factor $\mathrm{P}=\left(\cos \left(\mathrm{z}_{0}\right) / \cos (\mathrm{z})\right)^{2}$, where normally $\mathrm{z}_{0}=80^{\circ}$, and z is the maximum zenith distance of the source at two stations.

## Conclusion and discussion

The preliminary conclusions from this test are the following.

- The Xp, Yp and UT1 uncertainties grow with the increasing cut-off angle after $\sim 10^{\circ}$. Most probably, this reflects the fact that only about $6 \%$ of the total number of observations were made at the elevations below $10^{\circ}$. The Xc and Yc uncertainties and scatter depend on the CEA much less.
- Xp bias w.r.t. IGS slightly depends on the CEA, except the maximum tested CEA values, evidently unrealistic. In contrast, Yp bias substantially changes with increasing CEA. Most probably, this can be explained by the CONT05 network orientation, for which the longitude of the central meridian $\lambda_{0}=265^{\circ}$ just corresponds to the $Y$ direction of the terrestrial coordinate system.
- Some statistics such as the uncertainty and the scatter of the Xc and Yc, as well as the WRMS of Xp and Yp w.r.t. IGS have the minimum at the CEA around $\sim 15^{\circ}$, which is interesting and deserves a supplement investigation.
- As one can expect, the correlations between EOP comprising Xp and Yp grow with increasing CEA, but remain small due to good CONT05 network geometry. The same can be expected for the IVS2010 network. The correlation between Xc and Yc remain practically the same for all tested CEA, except the maximum tested CEA value, evidently unrealistic.
